ABSTRACT

New observational facilities are probing astrophysical transients such as stellar explosions and gravitational wave (GW) sources at ever increasing redshifts, while also revealing new features in source property distributions. To interpret these observations, we need to compare them to predictions from stellar population models. Such models require the metallicity-dependent cosmic star formation history (S(Z, z)) as an input. Large uncertainties remain in the shape and evolution of this function. In this work, we propose a simple analytical function for S(Z, z). Variations of this function can be easily interpreted, because the parameters link to its shape in an intuitive way. We fit our analytical function to the star-forming gas of the cosmological TNG100 simulation and find that it is able to capture the main behaviour well. As an example application, we investigate the effect of systematic variations in the S(Z,z) parameters on the predicted mass distribution of locally merging binary black holes (BBH). Our main findings are: I) the locations of features are remarkably robust against variations in the metallicity-dependent cosmic star formation history, and II) the low mass end is least affected by these variations. This is promising as it increases our chances to constrain the physics that governs the formation of these objects.

1. INTRODUCTION

Make sure to address the difference in rate beween this paper and (van Son 2022)! A myr-24 iad of astrophysical phenomena depend critically on the 25 rate of star formation throughout the cosmic history of 26 the Universe. Exotic transient phenomena, including 27 (pulsational) pair-instability supernovae, long gamma-28 ray bursts and gravitational wave (GW) events appear 29 to be especially sensitive to the metallicity at which star 30 formation occurs at different epochs throughout the Uni-31 verse (e.g., Langer et al. 2007; Fruchter et al. 2006; Ab-₃₂ bott et al. 2016). Gravitational astronomy in particular 33 has seen explosive growth in the number of detections 34 in the past decade (Abbott et al. 2018, 2020, 2021a), 35 while theoretical predictions vary greatly due to uncer-36 tainties in the aforementioned metallicity of star forma-37 tion (e.g., Santoliquido et al. 2021; Broekgaarden et al. 38 2021). In order to correctly model and interpret these 39 observations, it is thus fundamental to know the rate of

 $_{40}$ star formation at different metallicities throughout cos- $_{41}$ mic history; i.e. the metallicity-dependent cosmic star $_{42}$ formation history ($\mathcal{S}(Z,z)$, see also the recent review by $_{43}$ Chruślińska 2022). Throughout this work little z refers $_{44}$ to the redshift and Z to the metallicity of star formation. $_{45}$ It is difficult to observationally constrain the shape $_{46}$ of $\mathcal{S}(Z,z)$ – (see e.g., Chruślińska & Nelemans 2019; $_{47}$ Boco et al. 2021, for discussion of relevant observational $_{48}$ caveats). Even at low redshifts, the low metallicity part $_{49}$ of the distribution is poorly constrained (Chruślińska $_{50}$ et al. 2021). Nonetheless, several methods exist to es- $_{51}$ timate the metallicity-dependent cosmic star formation $_{52}$ history.

The first method is based on empirical scaling relations, linking galaxy properties like stellar mass M_{\star} , metallicity Z, and overall star-formation rate density SFRD(z), with the galaxy stellar mass function, GSMF (see e.g. Dominik et al. 2013). However, the applied methods to infer galaxy properties and subsequently scaling relations such as the MZ-relation differ greatly, which makes it difficult to interpret these results in a consistent way (e.g., Kewley & Ellison 2008; Maiolino & Mannucci 2019; Cresci et al. 2019). Moreover, observa-

63 tions are generally incomplete at high redshifts and low 64 galaxy luminosity (e.g., Chruślińska et al. 2021).

One can also directly extract the metallicity66 dependent cosmic star formation history from cosmo67 logical simulations (e.g. Mapelli et al. 2017; Briel et al.
68 2022a). However, these simulations currently lack the
69 resolution to resolve the lowest mass galaxies, and their
70 variations in S(Z,z) span a smaller range than those ob71 served in observationally-based models (Pakmor et al.
72 2022).

Alternatively, one can combine analytical models for the observed overall star-formation rate density, SFRD(z), like those from Madau & Dickinson (2014) for Madau & Fragos (2017), and convolve this with an assumed function for the shape of the cosmic metallicity density distribution, such as was was done in e.g., Langer & Norman (2006) and the phenomenological model in Neijssel et al. (2019).

In this work we follow the latter approach and propose a flexible analytical model for $\mathcal{S}(Z,z)$ that can be fit to the output of both cosmological simulations, and observational data constraints where available. In contrast to earlier work, we adopt a skewed-lognormal distribution of metallicities that can capture the asymmetry in the low and high metallicity tails.

The purpose of this proposed form is twofold. First 89 of all, the form we propose allows for an intuitive inter-90 pretation of the free parameters. This allows us to get 91 better insight of the impact of changes in these param-92 eters on the inferred ranges of astrophysical transients 93 (as we demonstrate in Section 4 using GW predictions as 94 an example). By adopting an analytical, parametrized 95 form for S(Z,z), the large uncertainties can be system-96 atically explored. Secondly, both the large complica-97 tions in observational constraints, and the many uncer-98 tainties in cosmological simulations call for a generalised 99 form of $\mathcal{S}(Z,z)$ that can be easily updated when new in-100 formation becomes available. In particular, the advent 101 of observations with the James Webb Space Telescope 102 promises a new era of high-redshift metallicity studies 103 of previously unexplored regimes (e.g., Sanders et al. 104 2022). We hope that this form will facilitate the flexibility needed to keep up with observations.

We describe our model for $\mathcal{S}(Z,z)$ in Section 2. We 107 fit our model to the star-forming gas in the Illustris TNG100 simulation in Section 3, and demonstrate an 109 example application of our model by systematically 110 varying the parameters that determine the shape of 111 $\mathcal{S}(Z,z)$ and investigate their impact on the local distribution of merging BBH masses in Section 4. We sum-113 marise our findings in Section 5.

Throughout this work, we adopt a universal Kroupa initial mass function (Kroupa 2001) with the mass limits $0.01-200{\rm M}_{\odot}$ and a flat $\Lambda{\rm CDM}$ cosmology with $\Omega_{\rm M}=0.31,~\Omega_{\Lambda}=0.69$ and $H_0=67.7{\rm km\,s^{-1}\,Mpc^{-1}}$ (Planck Collaboration et al. 2020).

2. A CONVENIENT ANALYTIC EXPRESSION FOR THE METALLICITY-DEPENDENT COSMIC STAR FORMATION HISTORY

119

120

121

135

We assume that the metallicity-dependent cosmic star formation history can be separated into two independent functions (as was assumed in e.g., Langer & Norman 2006, but cf. Chruślińska 2022 for a discussion on the validity on this assumption).

$$S(Z, z) = SFRD(z) \times \frac{dP}{dZ}(Z, z).$$
(1)

The first term is the star formation rate density, SFRD(z), that is the amount of mass formed in stars per unit time and per unit comoving volume at each redshift, z. The second term, $\mathrm{dP}/\mathrm{dZ}(Z,z)$, is a probability density distribution that expresses what fraction of star formation occurs at which metallicity, Z, at each redshift.

2.1. The cosmic metallicity density distribution

For the probability distribution of metallicities we draw inspiration from the approach by e.g., Neijssel et al. (2019) who used a log-normal distribution for their phenomenological model. Unfortunately, a simple log-normal distribution cannot capture the asymmetry that we see in the cosmological simulations, which show an extended tail in $\log_{10} Z$ towards low metallicity, combined with a very limited tail towards higher metallicity. To capture this behaviour we adopt a skewed-log-normal distribution instead. This is an extension of the normal distribution that introduces an additional shape parameter, α , that regulates the skewness (first introduced by O'Hagan & Leonard 149 1976).

The skewed-log-normal distribution of metallicities is defined as:

$$\frac{\mathrm{dP}}{\mathrm{dZ}}(Z,z) = \frac{1}{Z} \times \frac{\mathrm{dP}(Z,z)}{\mathrm{d}\ln Z}$$

$$= \frac{1}{Z} \times \frac{2}{\omega} \underbrace{\phi\left(\frac{\ln Z - \xi}{\omega}\right)}_{(a)} \underbrace{\Phi\left(\alpha \frac{\ln Z - \xi}{\omega}\right)}_{(b)}, \quad (2)$$

where (a) is the standard log-normal distribution, ϕ ,

$$\phi\left(\frac{\ln Z - \xi}{\omega}\right) \equiv \frac{1}{\sqrt{2\pi}} \exp\left\{-\frac{1}{2} \left(\frac{\ln Z - \xi}{\omega}\right)^2\right\}$$
 (3)

 $_{155}$ and (b) is the new term that allows for asymmetry, $_{156}$ which is equal to the cumulative of the log-normal dis- $_{157}$ tribution, Φ ,

$$\Phi\left(\alpha \frac{\ln Z - \xi}{\omega}\right) \equiv \frac{1}{2} \left[1 + \operatorname{erf}\left\{\alpha \frac{\ln Z - \xi}{\omega \sqrt{2}}\right\} \right]. \tag{4}$$

This introduces three parameters, α, ω and ξ , each of which may depend on redshift. The first parameter, α , is known as the "shape". It affects the skewness of the distribution and thus allows for asymmetries between metallicities that are higher and lower than the mean. The symmetric log-normal distribution is recovered for $\alpha = 0$. The second parameter, ω is known as the "scale". It provides a measure of the spread in metallicities at each redshift. Finally, ξ , is known as the "location", because this parameter plays a role in setting the mean of the distribution at each redshift.

The location and the mean of the metallicity distribution—171 To obtain a useful expression for the redshift dependence of the "location" $\xi(z)$ we first express the expectation value or mean metallicity at a given redshift

$$\langle Z \rangle = 2 \exp\left(\xi + \frac{\omega^2}{2}\right) \Phi\left(\beta \omega\right)$$
 (5)

175 where β is

174

176

188

158

$$\beta = \frac{\alpha}{\sqrt{1 + \alpha^2}}. (6)$$

177 (For a more extended derivation of the moments of the 178 skewed-log-normal, see e.g., Wang et al. (2019).)

For the evolution of the mean metallicity with redshift we follow Langer & Norman (2006) and the phenomenological model from Neijssel et al. (2019) in assuming that the mean of the probability density function of metallicities evolves with redshift as:

$$\langle Z \rangle \equiv \mu(z) = \mu_0 \cdot 10^{\mu_z \cdot z},\tag{7}$$

where μ_0 is the mean metallicity at redshift 0, and μ_z determines redshift evolution of the location. Equating this to Equation 5, we get an expression for $\xi(z)$,

$$\xi(z) = \ln\left(\frac{\mu_0 \cdot 10^{\mu_z \cdot z}}{2\Phi(\beta\,\omega)}\right) - \frac{\omega^2}{2}.\tag{8}$$

232

The scale (and variance) of the metallicity distribution—
We will also allow the "scale" ω to evolve with redshift in a similar manner,

$$\omega(z) = \omega_0 \cdot 10^{\omega_z \cdot z}.\tag{9}$$

where ω_0 is the width of the metallicity distribution at z=0, and z=0, are the redshift evolution of the scale.

Note that the width, w(z) is not the same as the variance. The variance, $\sigma^2(z)$, can be expressed as

$$\sigma^2(z) = \omega^2(z) \left(1 - \frac{2\beta^2}{\pi} \right) \tag{10}$$

Asymmetry of the metallicity distribution: α —The skewness α could in principle also be allowed to evolve with redshift (e.g., $\alpha(z) = \alpha(z=0)10^{\alpha_z \cdot z}$). However, we find no significant improvement over the simpler assumption where alpha is kept constant. Note that the redshift evolution of the 'scale' (eq. 9), already captures similar behaviour in our current formalism. We therefore adopt $\alpha = \alpha(z=0)$ and $\alpha_z = 0$.

In summary, Equation 2 becomes:

$$\frac{\mathrm{dP}}{\mathrm{dZ}}(Z,z) = \frac{2}{\omega(z)Z} \times \phi\left(\frac{\ln Z - \xi(z)}{\omega(z)}\right) \Phi\left(\alpha \frac{\ln Z - \xi(z)}{\omega(z)}\right) \tag{11}$$

where $\xi(z)$ and $\omega(z)$ are defined in Equations 8 and 9 respectively and we have assumed α to be constant.

2.2. The overall cosmic star formation rate density

For the star formation rate density, we assume the analytical form proposed by Madau & Dickinson (2014),

SFRD(z) =
$$\frac{d^2 M_{SFR}}{dt dV_c}(z) = a \frac{(1+z)^b}{1 + [(1+z)/c]^d}$$
 (12)

 $_{214}$ in units of $[{
m M}_{\odot}\,{
m yr}^{-1}\,{
m cMpc}^{-3}]$. This introduces four $_{215}$ parameters: a which sets the overal normalisation and $_{216}$ which has the same units as SFRD(z) and b,c and d $_{217}$ which are unitless and which govern the shape of the $_{218}$ overal cosmic star formation rate density with redshift.

Lastly, we combine equations 11 and 12 to form a full metallicity specific star formation rate density as described in equation 1.

223 3. FIT AGAINST COSMOLOGICAL SIMULATION

We fit our new functional form of $\mathcal{S}(Z,z)$ as defined by equations 1, 11 and 12 to the IllustrisTNG cosmological simulations. We simultaneously fit for the following nine free parameters $\alpha, \mu_0, \mu_z, \omega_0, \omega_z$, which govern the metallicity dependence and a,b,c and d, which set the overall star-formation rate density. Below we briefly discuss the IllustrisTNG simulations, and elaborate on our fitting procedure.

3.1. IllustrisTNG Cosmological simulations

Although here, we only fit our model to the TNG100 simulation, our prescription can be easily be used to fit other simulated or observational data of the metallicity-dependent cosmic star formation history.

¹ We provide a Jupyter notebook to facilitate this fit here: https://github.com/LiekeVanSon/SFRD_fit/blob/main/src/scripts/Notebooks/Fit_model_to_sfrdzZ.ipynb

The IllustrisTNG-project (or TNG in short) considers galaxy formation and evolution through large-scale cosmological hydrodynamical simulations (Springel et al. 2018; Marinacci et al. 2018; Nelson et al. 2018; Pillepich et al. 2018a; Naiman et al. 2018; Nelson et al. 2019a; Pillepich et al. 2019). Such simulations provide the tools to study parts of the Universe that are not easily accessible by observations. In particular of interest for this work, they simulate the high redshift enrichment of galaxies and the tail of low metallicity star formation at low redshift.

The models implemented in the publicly available 248 TNG simulations (Nelson et al. 2019b)² have lead to 249 250 many successes. These models where calibrated at the 251 resolution of the TNG100 simulation, hence TNG100 is 252 expected to provide the best overall agreement to global 253 properties (like the star formation rate density). This why we adopt the TNG100 simulation as our fidu-255 cial simulation. For a more extended discussion focused 256 on the processes that govern the creation, distribution 257 and mixing of metals in in the TNG simulations, we re-258 fer to Pakmor et al. (2022). In short, star formation in 259 the TNG simulations is calibrated against the Kennicutt-Schmidt relation (Schmidt 1959; Kennicutt 1989), using an effective equation of state (Springel & Hern-262 quist 2003). The stellar metallicity yields are an up-263 dated version of the original Illustris simulations as de-264 scribed in Pillepich et al. (2018b). Star particles deposit 265 metals into the gas through type Ia and type II super-266 novae, as well as through asymptotic giant branch stars. ²⁶⁷ The TNG simulations have been shown to match obser-²⁶⁸ vational constraints on the mass-metallicity relation of galaxies up to z=2 (Torrey et al. 2019), as well as iron 270 abundances (Naiman et al. 2018), metallicity gradients within galaxies at low redshift (Hemler et al. 2021), and 272 the reduction of star formation in the centers of star-273 forming galaxies (Nelson et al. 2021). Several studies 274 have used the TNG simulations to make predictions for 275 astronomical transient sources (e.g. Briel et al. 2022a; 276 Bayera et al. 2022; van Son et al. 2022). Out of the four $\mathcal{S}(Z,z)$ variations explored, Briel et al. (2022a) find that 278 TNG provides one of the best agreements between ob-279 served and predicted cosmic rates for electromagnetic 280 and gravitational-wave transients, when combined with their fiducial binary population synthesis model.

On the other hand, large uncertainties and crude approximations remain in all contemporary cosmological simulations, thus also in the TNG simulations. Generally, some of the chemical evolution of galaxies in

286 cosmological simulations is unresolved, and thus de-287 pends strongly on the implemented 'sub-grid physics'. 288 A known uncertainty is that dust is not included in the 289 TNG simulations, which could mean that metallicity of 290 the star-forming gas is overestimated. Feedback from ac-291 tive galactic nuclei is not well understood theoretically 292 and is described in an approximate manner (Springel 293 et al. 2005; Weinberger et al. 2017). Furthermore, all 294 stellar winds mass loss from massive stars, binary inter-295 actions and their ionising effects are ignored (e.g. Dray 296 et al. 2003; Smith 2014; Götberg et al. 2020; Doughty & ²⁹⁷ Finlator 2021; Farmer et al. 2021; Goswami et al. 2022). 298 Moreover, the uniform ionising UV background is turned 299 on abruptly at z=6. This crucially impacts the amount 300 of low metallicity star formation at high redshift as it 301 allows small galaxies to produce more stars than what 302 would be expected for a gradually increasing UV back-303 ground that reaches full strength at z=6. All these 304 uncertainties underline the need for a flexible approximation of the S(Z,z), that can be easily updated when 306 cosmological models and sub-grid physics are updated.

3.2. Choices and binning of the data

307

319

We fit equation 1 to the metallicity-dependent star formation rate of the star-forming gas in the TNG100 simulation. For this we use a binned version of the TNG data $\mathcal{S}(Z,z)_{\mathrm{sim}}$. We consider metallicities between $\log_{10} Z = -5$ to $\log_{10} Z = 0$ in 30 bins, where we use $\log_{10} Z_i$ to refer to the logarithmic centres of the bins. We ignore star formation in metallicities $\log_{10} Z \leq -5$ as this accounts for less than 1% of the total cosmic star formation rate in these simulations. We consider bins in redshifts between z=0 and z=10, with a step size of dz=0.05, where z_i refers to the centres of the bins.

3.3. Optimisation function

To find a solution we use a method based on the sum of the quadratic differences between the simulations and our fit function. Using a vanilla χ -squared approach does not serve our purposes very well as it does a poor job in fitting regions where the star formation is very low. Using a χ -squared approach on the logarithm of the function instead places far too much weight on trying to fit the star formation rate in regions where the rate is very low or not even significant. After experimenting, we find that the following approach gives us satisfactory results.

We first consider a given redshift z_j . For this redshift we compute the sum of the squared residuals between the cosmological simulation and our fit. This is effectively the square of the l^2 -norm:

$$\chi^{2}(z_{j}) \equiv \sum_{Z_{i}} \left(\mathcal{S}(Z_{i}, z_{j})_{\text{sim}} - \mathcal{S}(Z_{i}, z_{j})_{\text{fit}} \right)^{2}. \tag{13}$$

 $^{^2 \; \}mathrm{https://www.tng\text{-}project.org/}$

Here, the variable Z_i runs over all metallicity bins. We are particularly interested in properly fitting the low metallicity star formation at high redshifts. At high redshifts, the overall star-formation rate density is generally lower. To ensure that our fitting procedure gives sufficient weight to the behaviour at all redshifts, we introduce a penalisation factor to somewhat reduce the contribution of redshifts where the peak of cosmic star formation occurs, while increasing the weight at redshifts where the overall star-formation rate density is lower. To achieve this we divide $\chi^2(z_j)$ by the star formation $\sum_{Z_i} \mathcal{S}(Z_i, z_j)$ per redshift bin before adding the contribution of all redshifts. Our final expression for the cost function reads

$$\chi = \sum_{z_j} \frac{\chi^2(z_j)}{\sum_{Z_i} \mathcal{S}(Z_i, z_j)}$$
 (14)

To minimize this cost funciton, we use scipy optimize minimize from SciPy v1.6.3 which mplements the quasi-Newton method of Broyden, Fletcher, Goldfarb, and Shanno (BFGS, Nocedal & Wright 2006).

350

356

3.4. Resulting S(Z,z)

Our best fitting parameters are listed in Table 1. With these fit parameters, $\chi^2(z_j)$ is smaller than $2 \cdot 10^{-4}$ at any given redshift. We will refer to the $\mathcal{S}(Z,z)$ with the parameters listed in Table 1 as our fiducial model.

In Figure 1 we show our fiducial model at different redshifts and metallicities. We also show the overall starformation rate density SFRD(z) in Figure 2. In general,
our analytical model captures the metallicity-dependent
cosmic star formation history in the TNG100 simulations well (bottom panels of Figure 1). The skewedlog normal metallicity distribution is able to reproduce
the overall behaviour that is observed in TNG100 (bottom left panel, but cf. Pakmor et al. 2022, for an indepth discussion of low metallicity star formation in the
TNG50 simulation). Only minor features like the additional bump just above $\log_{10}(Z) = -2$ at redshift 2 are
missed. However, for our purposes, it is more important
to prioritise fitting the large scale trends, while we are
not so interested in smaller scale fluctuations.

Adopting a skewed-lognormal metallicity distribution allows for a tail of low metallicity star formation out to low redshifts. To emphasise the difference between a skewed-lognormal and a symmetric lognormal distribution, we show the phenomenological model from Neijssel et al. (2019) in dotted grey. Their model falls within the family of functions that is encompassed by our model

383 described in Section 2, but we note that their model is 384 distinctly different.³

Although our model preforms well at reproducing the 386 large scale trends seen in TNG, we acknowledge that 387 more complex features as suggested by some observa-388 tional studies could be missed. One example is that 389 the SFRD(z) shape we adopt from Madau & Dickinson 390 (2014) does not account for starburst galaxies (see dis-³⁹¹ cussion in Chruślińska et al. 2021). Moreover, our model 392 cannot capture inflection points in the mean metallicity, 393 because we assume both μ_0 and μ_z are constants with 394 redshift (equation 7). Contrarily, Chruślińska & Nelemans (2019) find an upturn in the amount of low metal-396 licity star formation above z = 4 if the power law of 397 the GSMF is allowed to evolve with redshift. Hence, 398 although our model is more broadly applicable than 399 previous models, in it's current form, it does not cap-400 ture the complete range of observationally-allowed varia-401 tions. Incorporating more complex functional forms for 402 our the mean metallicity could possibly capture such 403 behaviour, but this analysis is beyond the scope of this 404 paper.

405 4. APPLICATION: SYSTEMATIC VARIATIONS OF 406 $\mathcal{S}(Z,z)$ AND THE EFFECT ON THE MASS 407 DISTRIBUTION OF MERGING BBHS

We will now demonstrate the application of our analytical model by systematically varying the parameters in our fiducial S(Z,z) model, and investigate their effect on the local mass distribution of BBH mergers originating from isolated binaries.

We use the publicly available rapid binary population synthesis simulations presented in van Son et al tion prep). These simulations were run using version v02.26.03 of the open source COMPAS suite (Riley et al. 2022). COMPAS is based on algorithms that model the evolution of massive binary stars following Hurley et al. (2000, 2002) using detailed evolutionary models by Pols et al. (1998). We refer the reader to the methods section of van Son et al. (2022) for a detailed description of our adopted physics parameters and assumptions. Metallictities of each binary system were sampled from a smooth probability distribution to avoid artificial peaks in the BH mass distribution (e.g. Dominik et al. 2015; Kummer 2020). These simulations provide us with an estimate of

³ The phenomenological model from Neijssel et al. (2019) is recovered by adopting $\mu_0 = 0.035$, $\mu_z = -0.23$, $\omega_0 = 0.39$, $\omega_z = 0$, $\alpha = 0$, a = 0.01, b = 2.77, c = 2.9 and d = 4.7.

⁵ https://github.com/TeamCOMPAS/COMPAS

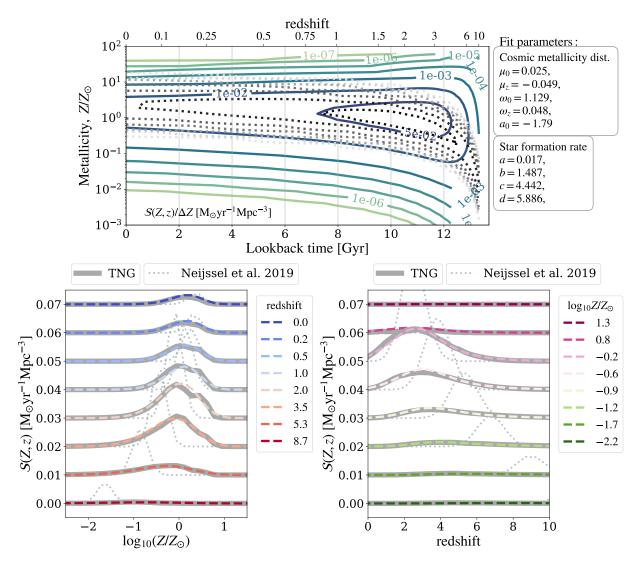

Figure 1. Our fiducial S(Z,z) model, adopting the best fitting parameters (listed on the top right) to fit the TNG100 simulations. The top panel shows the full two dimensional S(Z,z) linear in time. Contours range from $10^{-7}-10^{-2}\mathrm{M}_{\odot}\,\mathrm{yr}^{-1}\,\mathrm{Mpc}^{-3}$. The bottom left (right) panel shows slices of the distribution in redshift (metallicity). Each slice is displaced by $0.01\mathrm{M}_{\odot}\,\mathrm{yr}^{-1}\,\mathrm{Mpc}^{-3}$ (note the linear scale of S(Z,z) in the bottom panel). We show the TNG100 simulation data with thick gray lines. For comparison, we also show the phenomenological model from Neijssel et al. (2019) in all panels with grey dotted lines. The bottom panels show that our analytical model adequately captures the shape of the S(Z,z) from TNG100.

Table 1. Best fitting parameters for our S(Z, z) fit to TNG100 data.

dP/dZ	description	best fit	SFRD(z)	best fit
			$\mathrm{M}_{\odot}\mathrm{yr}^{-1}\mathrm{Mpc}^{-3}$	
μ_0	mean metallicity at $z = 0$	0.025 ± 0.001	a	0.02 ± 0.05
μ_z	z-dependence of the mean	-0.048 ± 0.001	b	1.48 ± 0.01
α	shape (skewness)	-1.767 ± 0.05	c	4.45 ± 0.01
ω_0	scale at $z = 0$	1.125 ± 0.005	d	5.90 ± 0.02
ω_z	z-dependence of the scale	0.048 ± 0.0001		

Table 2. Variations on S(Z,z). For every variation, we either swap the value of an individual $\mathrm{dP}/\mathrm{dZ}(Z,z)$ parameter, or exchange the set of four $\mathrm{SFRD}(z)$ parameters, and replace them by the the min/max values listed here. All other parameters are kept fixed at their fiducial value.

	min	fiducial	max

the yield of BBH mergers per unit of star-forming mass and metallicity.

We combine the aforementioned yield with variations of the fiducial $\mathcal{S}(Z,z)$ model described in this work. By integrating over cosmic history, we obtain the local merger rates of BBH systems, which allow us to construct the distribution of source properties at every redshift. We use the cosmic integration scheme that is part of the publicly available COMPAS suite. The details of this framework are described in Neijssel et al. (2019), but also in van Son et al. (2022), where more similar settings to this work are used.

4.1. Determining reasonable variations of S(Z,z)

439

We consider variations in both the shape of the cosmic metallicity density distribution $\mathrm{dP/dZ}(Z,z)$, and the shape of the overall star-formation rate density, SFRD(z). To determine the range that is reasonably allowed by observations, we compare our variations to the observation-based $\mathcal{S}(Z,z)$ models described in Chruślińska et al. (2021). An overview of the explored variations is shown in Table 2. Below we explain how we arrive at these values.

For the cosmic metallicity density distribution, we 450 vary every parameter that determines the shape of 451 dP/dZ(Z,z) independently (left two columns of Ta-452 ble 1), while keeping all other parameters fixed at 453 their fiducial value. For each variation, we inspect 454 the fraction of stellar mass that is formed at low-455 metallicity ($Z < 0.1Z_{\odot}$) versus the fraction of stellar

456 lar mass that is formed at high-metallicity $(Z > Z_{\odot})$, 457 for all star formation that occurred below a certain 458 threshold redshift. We compare this to the models 459 from Chruślińska et al. (2021) in Figure 5 in Ap-460 pendix A. We have chosen our variations such that 461 they span a reasonable range of cosmic metallic-462 ity density distributions as allowed by observation-463 based and cosmological simulations-based models. We use the models 214-f14SB-BiC_FMR270_F0H_z_dM.dat, 302-f14SB-Boco_FMR270_F0H_z_dM.dat 466 Chruślińska et al. (2021)⁶ as a representation of a very 467 low and high metallicity star formation realisation re-468 spectively. These models are the low and high metallic-469 ity extreme under their fiducial SFR-metallicity corre-470 lation, and so we will refer to them as Chr21_lowZ 471 and Chr21_highZ respectively from hereon. The 472 difference between these models lies in the as-473 sumptions in the underlying empirical galaxy re-474 lations. In general, low-mass galaxies contribute 475 to low-metallicity star formation and shift the 476 peak of $\mathcal{S}(Z,z)$ to lower metallicities. Chr21_lowZ 477 is characterised by a star formation-galaxy mass 478 relation that is flat at high galaxy masses (re-479 ducing the star formation rate for the highest-480 mass galaxies), a galaxy stellar mass function 481 that evolves with redshift (predicting an in-482 creasing number density of low-mass galaxies), 483 and a galaxy mass-metallicity relation following 484 Pettini & Pagel (2004). This model further ap-485 proximates the contribution of starburst galaxies 486 following Bisigello et al. (2018) and Caputi et al. 487 (2017). Including starbursts shift the peak of 488 S(Z,z) to lower metallicities and broadens the 489 low metallicity part of the distribution. On 490 the other hand, Chr21_highZ assumes the star 491 formation-galaxy mass relation does not flatten 492 towards higher galaxy masses, a galaxy stellar 493 mass function that is constant over redshift, 494 and a galaxy mass-metallicity relation following 495 Kobulnicky & Kewley (2004). Lastly, this model 496 adopts the starburst prescription from Boco 497 et al. (2021), which produces results that are 498 similar to models without starburst galaxies.

For every variation of our model, we inspect both the full S(Z,z) and slices at redshifts z=0,0.5,3.0 and 6 by eye. At each slice we compare our model variation to Chr21_lowZ and Chr21_highZ, and ensure that none of our variations significantly exceeds these extremes in

⁶ These models including a detailed description of their contents are publicly available at https://ftp.science.ru.nl/astro/mchruslinska/Chruslinska_et_al_2021/

525

541

 $\mathcal{S}(Z,z)$. This also serves as a sanity check for the overall star-formation rate density.

Lastly, we consider two variations of the overall starformation rate density, SFRD(z), where we keep the metallicity distribution dP/dZ(Z,z) fixed, but vary all four SFRD(z) parameters at once (right two columns of 510 Table 1). We use Figure 11 from Chruślińska et al. (2021) to determine approximate upper and lower 512 bounds to the overall star-formation rate density. We 513 choose Madau & Fragos (2017) as an approximation of 514 the lower limit. For the upper limit, we use the upper 515 edge of models that adopt starbursts following 516 Bisigello et al. (2018) and Caputi et al. (2017) (SB: B18/C17), combined with a non-evolving low-518 mass end of the galaxy stellar mass function (shown as 519 a thick brown line in Fig. 11 of Chruślińska et al. 2021, 520 and described in their table B1). To approximate these 521 models, we fit equation 12 by eye to the broken power ₅₂₂ law description of this model as presented in appendix 523 B1 of Chruślińska et al. (2021). We show all SFRD(z)524 variations in Figure 2.

526 4.2. The effect of the $\mathcal{S}(Z,z)$ on the primary masses of merging BBH

To isolate the effect of the S(Z,z) from the effects of different formation channels, we split the data from van Son et al. (2022) between the stable mass transfer channel (e.g., van den Heuvel et al. 2017; Inayoshi et al. 2017; Bavera et al. 2021; Marchant et al. 2021; Gallegos-Garcia et al. 2021; van Son et al. 2022), and the 'classical' common-envelope channel (or CE channel, e.g., Belczynski et al. 2007; Postnov & Yungelson 2014; Belczynski et al. 2016; Vigna-Gómez et al. 2018). These channels are distinguished based on whether the binary system has experienced a common envelope phase (CE channel) or only stable mass transfer (stable channel in short from now on).

In Figures 3 and 4, we show the resulting primary mass distribution of merging BBHs from the stable channel and CE channel respectively. The primary (secondary) component refers to the more (less) massive component of merging BBHs. Each panel varies one aspect of the S(Z,z). In the first five panels of Figures 3 and 4, we vary one of the parameters that determine the shape of the probability density distribution of metallicities, while keeping all other values fixed at their fiducial values. In the last panel of Figures 3 and 4, we vary the shape of the overall star-formation rate densities, SFRD(z), to one of the variations shown in Figure

⁵⁵⁴ 2, while keeping the probability density distribution of metallicities fixed.

The first thing we note is that the location of the 557 features in the primary mass distribution are robust s₅₅₈ against variations in S(Z,z). For the stable channel, 559 two features are visible in all variations: a peak at $_{560}~M_{\rm BH,1} \approx 9 {\rm M}_{\odot}$ and a bump at $M_{\rm BH,1} \approx 22 {\rm M}_{\odot}$. Two 561 more features are visible in at the high mass end for almost all S(Z,z); a knee at $M_{\rm BH,1} \approx 35 {\rm M}_{\odot}$ and another ₅₆₃ bump at $M_{\rm BH,1} \approx 45 {\rm M}_{\odot}$. Although the locations of 564 these features are constant, the features themselves can 565 disappear for variations that suppress the rate of high 566 mass BHs (e.g., dashed lines in the top panels of Fig. 567 3). Similarly, the CE channel displays a kink in the dis-568 tribution at about $9M_{\odot}$, and a peak at approximately $_{569}~M_{\rm BH,1} \approx 17 \rm M_{\odot}$ for all variations. The latter peak is 570 the global peak of the mass distribution in almost all 571 variations.

The finding that the locations of features in the mass of distribution do not change for different $\mathcal{S}(Z,z)$ is con-574 sistent with earlier work. Recent work by Chruślińska 575 (2022) showed that, when comparing two very different 576 models of S(Z,z) (their Figure 5), the location of the peaks remains the same, even though the normalisation 578 between the two BBH merger rates is completely dif-579 ferent. Furthermore, Broekgaarden et al. (2021) show 580 the probability distribution of chirp masses for BBHs 581 in their Fig. 4. Although features can disappear when the S(Z,z) prohibits the formation of certain (typically 583 higher) mass BHs, the *location* of features remains the 584 same. This implies that the locations of features in 585 the mass distribution of BBHs are determined by the 586 formation channel and its underlying stellar and binary 587 physics. The locations of features could therefore serve 588 as sign posts of the underlying physics.

590 Second, we see that the low mass end of the pri-591 mary mass distribution is relatively robust against vari-592 ations in $\mathcal{S}(Z,z)$. To quantify this, we annotate the 593 ratio between the maximum and minimum rate at three ⁵⁹⁴ reference masses; $M_{\rm BH,1}=10,25,~{\rm and}~40{\rm M}_{\odot}.$ $M_{\rm BH,1}=10{\rm M}_{\odot},$ we find that the rate changes by at 596 most a factor of about 3.7 for the stable channel, and 597 at most about a factor of 3.8 for the CE channel. On 598 the other hand, the change in rate at $M_{\rm BH,1}=40{\rm M}_{\odot}$ 599 can be as high as a factor of about 200 and 150 for the 600 stable and CE channels, respectively. The lowest mass ₆₀₁ BHs are least affected by the S(Z,z) because they can 602 be formed from all metallicities above $Z \gtrsim 10^{-3}$ (see 603 e.g., Figures 7 and 13 from van Son et al. 2022). The for rate of star formation at metallicities above $\gtrsim 10^{-3}$ is 605 observationally relatively well constrained for redshifts

589

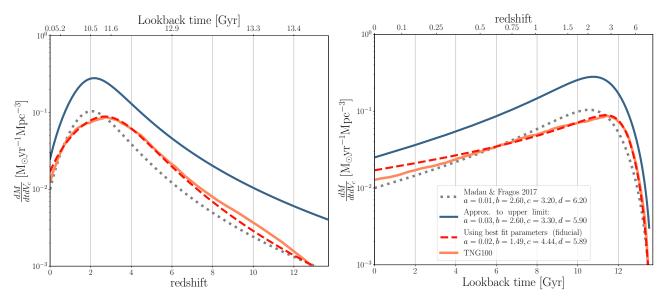

Figure 2. Comparison of several overall star-formation rate densities, SFRD(z), with redshift (left panel) and with lookback time (right panel). The solid orange and dashed red lines respectively show the star formation data from TNG100 and our corresponding fit adopting eq. 12 (fiducial model). The dotted gray and solid blue lines are variations of eq. 12 used to approximate the lower and upper edge of possible star-formation histories. The dotted gray line shows the model from Madau & Fragos (2017), while the solid blue line mimics the behaviour of the powerlaw-fit to the SB: B18/C17 variations with a non-evolving low-mass end of the galaxy stellar mass function from Chruślińska et al. (2021).

below 0.5 (which comprises the past 5 Gyr of star formation). This is reflected in the top panel of Figure 5: all models show that 10% or less of the stellar mass was formed at a metallicity below $Z/10 \approx 0.0014$, or in other words, about 90% or more of the stellar mass was formed at a metallicity above Z/10. Hence the lowest mass BHs derive from the least uncertain parts of the $\mathcal{S}(Z,z)$. The low-mass end of the mass distribution of merging double compact objects will also provide a particularly powerful cosmological constraint in the era of third generation gravitational wave telescopes (María Ezquiaga & Holz 2022). Our finding that the low mass end is more robust against variations in $\mathcal{S}(Z,z)$ supports this claim.

Parameter variations that affect shape of S(Z,z) at 620 low redshift primarily change the normalisation of the mass distribution. This is the case for variations of the width of the cosmic metallicity density distribution at =0 (ω_0), the mean metallicity of the cosmic metal-625 licity density distribution at z=0 (μ_0), and the skew-626 ness of the cosmic metallicity density distribution (α , 627 left columns of Figures 3 and 4). To emphasise this 628 point, we annotate the total BBH merger rate at redshift 629 0.2, $\mathcal{R}_{0,2}$, in the legends of Figures 3 and 4 (0.2 is the 630 redshift where the observations are best constrained Ab-631 bott et al. 2021b). Variations that increase the amount 632 of star formation at low metallicity (i.e. for a low mean metallicity $\mu_0=0.007$ and a wide metallicity distribu- $\omega_0 = 2.0$) increase the predicted BBH merger rate.

This is consistent with other work that finds merging BBHs form more efficiently at low metallicities (e.g. Bel-czynski et al. 2010; Stevenson et al. 2017; Mapelli et al. 2017; Chruślińska et al. 2019; Broekgaarden et al. 2021). A more skewed cosmic metallicity density distribution pushes the peak of the distribution to higher metallicities and thus forms more stars at high metallicity when compared to a symmetric distribution. Hence, the local rate of BBH mergers is lower for the skewed distribution ($\alpha = -6$) with respect to the symmetric variation $\alpha = 0.0$.

Changing the overall star-formation rate density $_{647}$ (SFRD(z), bottom right panels of Figures 3 and 4) also 648 affects the normalisation of the mass distribution, but 649 has a smaller effect than the width and the mean of the 650 cosmic metallicity density distribution at z=0 (ω_0 and ₆₅₁ μ_0). This underlines the importance of the amount of 652 low-metallicity star formation (e.g., Chruślińska 2022), 653 and is furthermore in line with findings from Tang et al. 654 (2020). As discussed in Section 4.1, we use Madau & 655 Fragos (2017) and the solid blue line in Figure 2 as an 656 approximate lower and upper bound to the SFRD(z) 657 respectively. The overall cosmic star formation rate 658 density from Madau & Fragos (2017) is very similar to 659 our fiducial model (Figure 2), and the differences be-660 tween the resulting mass distributions are correspond-661 ingly small. Our approximation of the upper limit to the allowed SFRD(z) leads to an overall increase of the 663 BBH merger rate by a factor of about 3.

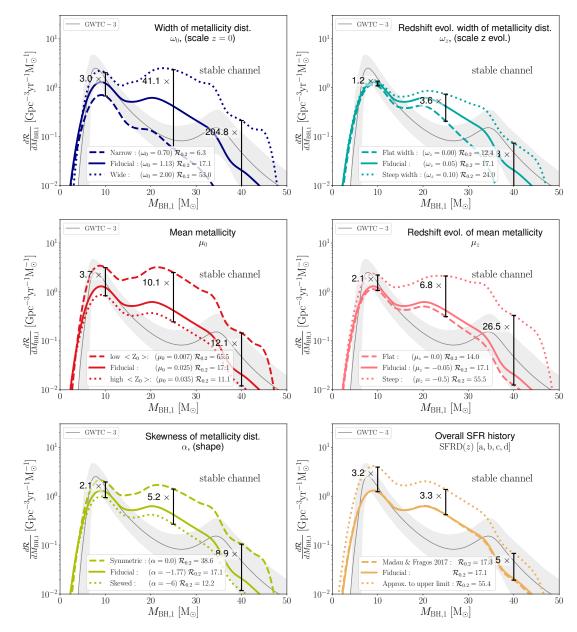

Figure 3. The primary mass distribution of merging BBH systems from the stable mass transfer channel for several variations in S(Z,z). The first five panels show variations of the cosmic metallicity density distribution dP/dZ(Z,z), eq. 11, (parameters listed in the first three columns of Table 1), where we vary one parameter at a time while keeping the rest fixed at their fiducial value. The bottom right panel shows variations in the magnitude of the star formation rate with redshift; i.e. SFRD(z). For the latter we vary the four fiducial parameters of SFRD(z) simultaneously (last two columns of Table 1). All panels are shown at a reference redshift of z=0.2, with the corresponding predicted BBH merger rate indicated in the legend. For reference, we show the power-law + peak model from Abbott et al. (2021b) in grey. We annotate the relative change in the rate at three reference masses: $10M_{\odot}$, $25M_{\odot}$ and $40M_{\odot}$.

Parameters that change the evolution of the metallic-665 ity distribution $\mathrm{dP}/\mathrm{dZ}(Z,z)$ with redshift, such as the 666 redshift dependence of the with and mean; ω_z and μ_z 667 (top right and centre right panels of Figures 3 and 4) 668 primarily affect the high mass end of the stable channel. 669 We understand this as an effect of the different delay 670 time distributions for both formation channels. Since 671 both, ω_z and μ_z influence the amount of low metallicity 672 stellar mass formed at high redshifts they will mostly af-673 fect systems with longer delay times. The stable channel 674 has been shown to produce more high mass BHs with 675 longer delay times when compared to the CE channel 676 (van Son et al. 2022; Briel et al. 2022b). Hence we find 677 these variations affect the slope of the high mass end of 678 the BBH mass distribution for the stable channel, while 679 they have a relatively small impact on the CE channel.

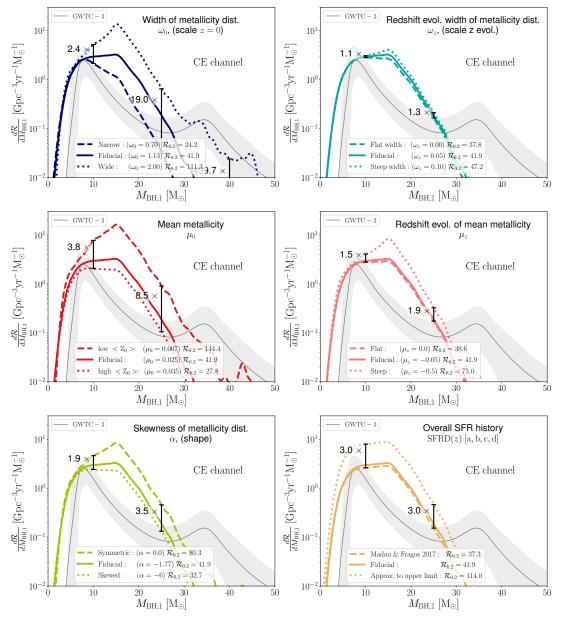

Figure 4. Same as Figure 3, but for the Common Envelope channel. These figures show that the low mass end of the primary mass distribution is least affected by the adopted S(Z, z). Moreover, the *location* of features in the mass distribution are robust against all explored variations.

5. DISCUSSION & SUMMARY

We present a flexible analytic expression for the metallicity-dependent cosmic star formation history, S(Z,z) (equations 1, 11 and 12). An analytical expression allows for controlled experiments of the effect of S(Z,z) on dependent values, such as the rate and mass distribution of merging BBHs. The model presented in this work adopts a skewed-lognormal for the distribution of metallicities at every redshift (dP/dZ(Z,z)).

The model can capture the general behaviour of cosmological simulations, such as TNG100—Our analytical expression

for $\mathcal{S}(Z,z)$ is composed of a cosmic metallicity density distribution that is determined by a mean, scale and skewness and their redshift dependence, as well as parameters governing the overall star-formation rate density. We fit our analytical expression for $\mathcal{S}(Z,z)$ to the star-forming gas in the TNG100 simulation, and provide the best fit parameters in Table 1. We show that our model captures the shape and general behaviour of the cosmological simulations well (Figure 1). Although our model is more broadly applicable than previous models, we acknowledge that it does not capture the *complete* range of observationally-allowed variations in it's cur-

703 rent form. Incorporating more complex functions for 704 the redshift evolution of the metallicity could solve this 705 issue, but this is left for future research.

The model allows for a controlled experiment on the effect of S(Z,z) on the local distribution of merging BBH—As an example, we use our model to calculate the local rate and mass distribution of the more massive components from merging BBHs $(M_{\rm BH,1})$ in Figures 3 and 4. We systematically vary all five parameters that shape the cosmic metallicity density distribution, and explore two additional variations of the overall star-formation rate density SFRD(z). Our main findings are as follows:

- The locations of features in the distribution of primary BH masses are robust against variations in S(Z,z). The location of features in the mass distribution of BHs could thus be used as sign posts of their formation channel.
- For all variations, the low mass end of the mass distribution is least influenced by changes in the S(Z,z). This is because the lowest mass BHs can be formed from all metallicities above $Z\gtrsim 10^{-3}$, for which the star formation rate is relatively well constrained in the recent Universe. This suggests that the lower end of the BH mass distribution (component masses of $\leq 15 {\rm M}_{\odot}$) is potentially very powerful for constraining the physics of the formation channels, irrespective of the cosmic star formation rate uncertainties.
- The metallicity distribution of star formation at low redshift primarily impacts the normalisation of the BBH merger rate. Changing the overall star-formation rate density, SFRD(z) also affects the rate, but to a lesser degree. This shows that low-metallicity star formation at low redshifts dominates the overall normalisation of the BBH merger rate.
- Parameters that influence the redshift evolution of the mean and the width of the metallicity distribution affect the slope of the high mass end of the primary BH mass distribution for the stable chan-

nel. This reflects the longer delay times of the stable channel with respect to the CE channel.

The flexibility of the model presented in this work can rate capture the large uncertainties that remain in the shape rate and normalisation of the metallicity-dependent cosmic star formation history. Our hope is that this expression will provide a useful starting point for making predictions and comparisons with observations.

APPENDIX

A. DETERMINING REASONABLE VARIATIONS OF THE S(Z, z)

To determine reasonable variations of our fiducial model for S(Z, z), we compute the fraction of low and high metallicity stellar mass formed for redshifts below z < 0.5, z < 3.0 and z < 10. We show the results in Figure 5, which is an adaptation of Fig. 2 in Pakmor et al. (2022), which in turn builds on Fig. 9 from Chruślińska & Nelemans (2019).

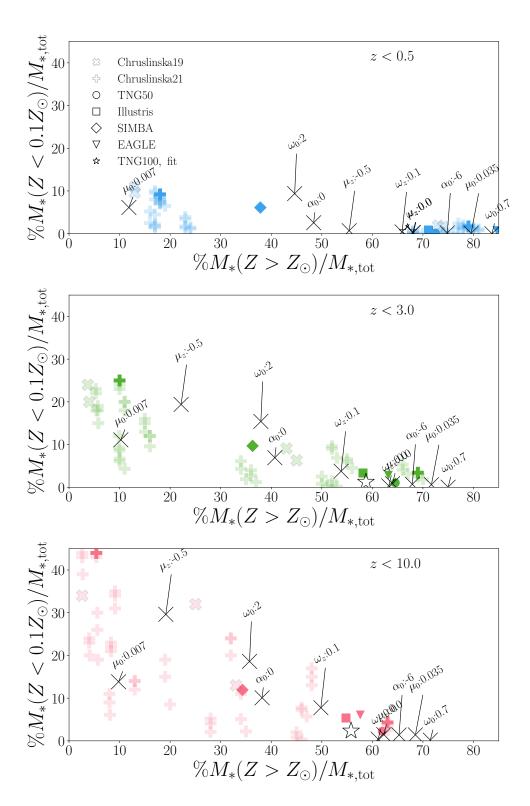

Figure 5. Percentage of stellar mass formed at low metallicity ($Z < 0.1Z_{\odot}$), versus high metallicity ($Z > Z_{\odot}$) for all star formation below a certain threshold redshift: z < 0.5 (top), z < 3.0 (middle) and z < 10 (bottom). Data from observation-based variations are shown with semi-transparent thick crosses, (Chruślińska & Nelemans 2019) and semi-transparent thick plus signs (Chruślińska et al. 2021), the low- and high-metallicity extremes are indicated with opaque symbols. For data from cosmological simulations, we follow Pakmor et al. (2022) and show Illustris (Vogelsberger et al. 2014, squares), Simba (Davé et al. 2019, diamonds), EAGLE (Schaye et al. 2015, triangles), TNG50 and TNG100 (Springel et al. 2018, filled and open circles respectively). Black thin crosses display variations of the cosmic metallicity density distribution that is part of our fiducial S(Z,z). The parameter that is varied with respect to the fiducial and its new value are annotated. This shows that our S(Z,z) variations span the range of reasonable cosmic metallicity density distributions as determined by observation-based and cosmological simulations-based models.
