ABSTRACT

New observational facilities are probing astrophysical transients such as stellar explosions and gravitational wave (GW) sources at ever increasing redshifts, while also revealing new features in source property distributions. To interpret these observations, we need to compare them to predictions from stellar population models. Such models require the metallicity-dependent cosmic star formation history (S(Z,z)) as an input. Large uncertainties remain in the shape and evolution of this function. In this work, we propose a simple analytical function for S(Z,z). Variations of this function can be easily interpreted, because the parameters link to its shape in an intuitive way. We fit our analytical function to the star-forming gas of the cosmological TNG100 simulation and find that it is able to capture the main behaviour well. As an example application, we investigate the effect of systematic variations in the S(Z,z) parameters on the predicted mass distribution of locally merging binary black holes (BBH). Our main findings are: I) the locations of features are remarkably robust against variations in the metallicity-dependent cosmic star formation history, and II) the low mass end is least affected by these variations. This is promising as it increases our chances to constrain the physics that governs the formation of these objects.

1. INTRODUCTION

A myriad of astrophysical phenomena depend criti-23 cally on the rate of star formation throughout the cosmic 24 history of the Universe. Exotic transient phenomena, 25 including (pulsational) pair-instability supernovae, long 26 gamma-ray bursts and gravitational wave (GW) events 27 appear to be especially sensitive to the metallicity at 28 which star formation occurs at different epochs through-²⁹ out the Universe (e.g., Langer et al. 2007; Fruchter et al. 30 2006; Abbott et al. 2016). Gravitational astronomy in 31 particular has seen explosive growth in the number of 32 detections in the past decade (Abbott et al. 2018, 2020, 33 2021a), while theoretical predictions vary greatly due to 34 uncertainties in the aforementioned metallicity of star 35 formation (e.g., Santoliquido et al. 2021; Broekgaarden 36 et al. 2021). In order to correctly model and interpret 37 these observations, it is thus fundamental to know the 38 rate of star formation at different metallicities through-39 out cosmic history; i.e. the metallicity-dependent cosmic

⁴⁰ star formation history (S(Z, z), see also the recent re-⁴¹ view by Chruślińska 2022). Throughout this work little ⁴² z refers to the redshift and Z to the metallicity of star ⁴³ formation.

It is difficult to observationally constrain the shape of S(Z,z) – (see e.g., Chruślińska & Nelemans 2019; Boco et al. 2021, for discussion of relevant observational caveats). Even at low redshifts, the low metallicity part of the distribution is poorly constrained (Chruślińska et al. 2021). Nonetheless, several methods exist to estimate the metallicity-dependent cosmic star formation history.

The first method is based on empirical scaling relations, linking galaxy properties like stellar mass M_{\star} , metallicity Z, and overall star-formation rate density SFRD(z), with the galaxy stellar mass function, GSMF (see e.g. Dominik et al. 2013). However, the applied methods to infer galaxy properties and subsequently scaling relations such as the MZ-relation differ greatly, which makes it difficult to interpret these results in a consistent way (e.g., Kewley & Ellison 2008; Maiolino & Mannucci 2019; Cresci et al. 2019). Moreover, observations are generally incomplete at high redshifts and low galaxy luminosity (e.g., Chruślińska et al. 2021).

One can also directly extract the metallicitydependent cosmic star formation history from cosmological simulations (e.g. Mapelli et al. 2017; Briel et al. 2022a). However, these simulations currently lack the resolution to resolve the lowest mass galaxies, and their variations in S(Z,z) span a smaller range than those obresolved in observationally-based models (Pakmor et al. 12022).

Alternatively, one can combine analytical models for the observed overall star-formation rate density, SFRD(z), like those from Madau & Dickinson (2014) for Madau & Fragos (2017), and convolve this with an assumed function for the shape of the cosmic metallicity density distribution, such as was was done in e.g., Langer & Norman (2006) and the phenomenological model in Neijssel et al. (2019).

In this work we follow the latter approach and propose a flexible analytical model for $\mathcal{S}(Z,z)$ that can be fit to the output of both cosmological simulations, and observational data constraints where available. In contrast to earlier work, we adopt a skewed-lognormal distribution of metallicities that can capture the asymmetry in the low and high metallicity tails.

The purpose of this proposed form is twofold. First 88 of all, the form we propose allows for an intuitive inter-89 pretation of the free parameters. This allows us to get 90 better insight of the impact of changes in these param-91 eters on the inferred ranges of astrophysical transients 92 (as we demonstrate in Section 4 using GW predictions as 93 an example). By adopting an analytical, parametrized ₉₄ form for S(Z,z), the large uncertainties can be system-95 atically explored. Secondly, both the large complica-96 tions in observational constraints, and the many uncer-97 tainties in cosmological simulations call for a generalised 98 form of S(Z,z) that can be easily updated when new in-99 formation becomes available. In particular, the advent 100 of observations with the James Webb Space Telescope promises a new era of high-redshift metallicity studies 102 of previously unexplored regimes (e.g., Sanders et al. 103 2022). We hope that this form will facilitate the flexibility needed to keep up with observations. The model 105 described in this work is incorporated in the pub-106 licly available 'Cosmic Integration' suite of the COMPAS code.1 107

We describe our model for S(Z,z) in Section 2. We fit our model to the star-forming gas in the Illustris TNG100 simulation in Section 3, and demonstrate an example application of our model by systematically

¹¹² varying the parameters that determine the shape of ¹¹³ S(Z,z) and investigate their impact on the local distri¹¹⁴ bution of merging BBH masses in Section 4. We sum¹¹⁵ marise our findings in Section 5.

Throughout this work, we adopt a universal Kroupa initial mass function (Kroupa 2001) with the mass limits 0.01 – 200 M_{\odot} and a flat Λ CDM cosmology with $\Omega_{\rm M}=$ 0.31, $\Omega_{\Lambda}=0.69$ and $H_0=67.7{\rm km\,s^{-1}\,Mpc^{-1}}$ (Planck Collaboration et al. 2020).

2. A CONVENIENT ANALYTIC EXPRESSION FOR THE METALLICITY-DEPENDENT COSMIC STAR FORMATION HISTORY

121

122

123

129

We assume that the metallicity-dependent cosmic star formation history can be separated into two independent functions (as was assumed in e.g., Langer & Norman 2006, but cf. Chruślińska 2022 for a discussion on the validity on this assumption).

$$S(Z, z) = SFRD(z) \times \frac{dP}{dZ}(Z, z).$$
 (1)

¹³⁰ The first term is the star formation rate density, ¹³¹ SFRD(z), that is the amount of mass formed in stars ¹³² per unit time and per unit comoving volume at each ¹³³ redshift, z. The second term, dP/dZ(Z,z), is a probability density distribution that expresses what fraction of star formation occurs at which metallicity, Z, at each ¹³⁶ redshift.

2.1. The cosmic metallicity density distribution

For the probability distribution of metallicities we draw inspiration from the approach by e.g., Neijssel et al. (2019) who used a log-normal distribution for their phenomenological model. Unfortunately, a simple log-normal distribution cannot capture the asymmetry that we see in the cosmological simulations, which show an extended tail in $\log_{10} Z$ towards low metallicity, combined with a very limited tail towards higher metallicity. To capture this behaviour we adopt a skewed-log-normal distribution instead. This is an extension of the normal distribution that introduces an additional shape parameter, α , that regulates the skewness (first introduced by O'Hagan & Leonard 1976).

The skewed-log-normal distribution of metallicities is defined as:

$$\frac{\mathrm{dP}}{\mathrm{dZ}}(Z,z) = \frac{1}{Z} \times \frac{\mathrm{dP}(Z,z)}{\mathrm{d}\ln Z}$$

$$= \frac{1}{Z} \times \frac{2}{\omega} \underbrace{\phi\left(\frac{\ln Z - \xi}{\omega}\right)}_{(a)} \underbrace{\Phi\left(\alpha\frac{\ln Z - \xi}{\omega}\right)}_{(b)}, \quad (2)$$

https://github.com/TeamCOMPAS/COMPAS/tree/dev/utils/ CosmicIntegration

where (a) is the standard log-normal distribution, ϕ ,

$$\phi\left(\frac{\ln Z - \xi}{\omega}\right) \equiv \frac{1}{\sqrt{2\pi}} \exp\left\{-\frac{1}{2} \left(\frac{\ln Z - \xi}{\omega}\right)^2\right\}$$
 (3)

 $_{157}$ and (b) is the new term that allows for asymmetry, $_{158}$ which is equal to the cumulative of the log-normal dis- $_{159}$ tribution, Φ ,

$$\Phi\left(\alpha \frac{\ln Z - \xi}{\omega}\right) \equiv \frac{1}{2} \left[1 + \operatorname{erf}\left\{\alpha \frac{\ln Z - \xi}{\omega \sqrt{2}}\right\} \right]. \tag{4}$$

This introduces three parameters, α, ω and ξ , each of which may depend on redshift. The first parameter, α , is known as the "shape". It affects the skewness of the distribution and thus allows for asymmetries between metallicities that are higher and lower than the mean. The symmetric log-normal distribution is recovered for $\alpha=0$. The second parameter, ω is known as the "scale". It provides a measure of the spread in metallicities at each redshift. Finally, ξ , is known as the "location", because this parameter plays a role in setting the mean of the distribution at each redshift.

The location and the mean of the metallicity distribution—
To obtain a useful expression for the redshift dependence of the "location" $\xi(z)$ we first express the expectation value or mean metallicity at a given redshift

$$\langle Z \rangle = 2 \exp\left(\xi + \frac{\omega^2}{2}\right) \Phi\left(\beta \omega\right)$$
 (5)

177 where β is

186

190

160

$$\beta = \frac{\alpha}{\sqrt{1 + \alpha^2}}.\tag{6}$$

179 (For a more extended derivation of the moments of the skewed-log-normal, see e.g., Wang et al. (2019).)

For the evolution of the mean metallicity with redshift we follow Langer & Norman (2006) and the phenomenological model from Neijssel et al. (2019) in assuming that the mean of the probability density function of metallist licities evolves with redshift as:

$$\langle Z \rangle \equiv \mu(z) = \mu_0 \cdot 10^{\mu_z \cdot z},\tag{7}$$

where μ_0 is the mean metallicity at redshift 0, and μ_z determines redshift evolution of the location. Equating this to Equation 5, we get an expression for $\xi(z)$,

$$\xi(z) = \ln\left(\frac{\mu_0 \cdot 10^{\mu_z \cdot z}}{2\,\Phi(\beta\,\omega)}\right) - \frac{\omega^2}{2}.\tag{8}$$

The scale (and variance) of the metallicity distribution—
192 We will also allow the "scale" ω to evolve with redshift
193 in a similar manner,

$$\omega(z) = \omega_0 \cdot 10^{\omega_z \cdot z}. \tag{9}$$

where ω_0 is the width of the metallicity distribution at z = 0, and ω_z the redshift evolution of the scale.

Note that the width, w(z) is not the same as the variance. The variance, $\sigma^2(z)$, can be expressed as

$$\sigma^2(z) = \omega^2(z) \left(1 - \frac{2\beta^2}{\pi} \right) \tag{10}$$

Asymmetry of the metallicity distribution: α —The skewness α could in principle also be allowed to evolve with redshift (e.g., $\alpha(z)=\alpha(z=0)10^{\alpha_z\cdot z}$). However, we find no significant improvement over the simpler assumption where alpha is kept constant. Note that the redshift evolution of the 'scale' (eq. 9), already captures similar behaviour in our current formalism. We therefore adopt $\alpha=\alpha(z=0)$ and $\alpha_z=0$.

In summary, Equation 2 becomes:

199

215

234

$$\boxed{\frac{\mathrm{dP}}{\mathrm{dZ}}(Z,z) = \frac{2}{\omega(z)Z} \times \phi\left(\frac{\ln Z - \xi(z)}{\omega(z)}\right) \Phi\left(\alpha \frac{\ln Z - \xi(z)}{\omega(z)}\right)}$$
(11)

where $\xi(z)$ and $\omega(z)$ are defined in Equations 8 and 9 respectively and we have assumed α to be constant.

212 2.2. The overall cosmic star formation rate density

For the star formation rate density, we assume the analytical form proposed by Madau & Dickinson (2014),

SFRD(z) =
$$\frac{d^2 M_{SFR}}{dt dV_c}(z) = a \frac{(1+z)^b}{1 + [(1+z)/c]^d}$$
 (12)

 216 in units of $[{
m M}_{\odot}\,{
m yr}^{-1}\,{
m cMpc}^{-3}]$. This introduces four parameters: a which sets the overal normalisation and 218 which has the same units as SFRD(z) and b,c and d 219 which are unitless and which govern the shape of the 220 overal cosmic star formation rate density with redshift.

Lastly, we combine equations 11 and 12 to form a full metallicity specific star formation rate density as described in equation 1.

225 3. FIT AGAINST COSMOLOGICAL SIMULATION

We fit our new functional form of $\mathcal{S}(Z,z)$ as defined by equations 1, 11 and 12 to the IllustrisTNG cosmological simulations. We simultaneously fit for the following nine free parameters $\alpha, \mu_0, \mu_z, \omega_0, \omega_z$, which govern the metallicity dependence and a,b,c and d, which set the overall star-formation rate density. Below we briefly discuss the IllustrisTNG simulations, and elaborate on our fitting procedure.

3.1. IllustrisTNG Cosmological simulations

Although here, we only fit our model to the TNG100 simulation, our prescription can be easily be used to fit other simulated or observational data of the metallicity-dependent cosmic star formation history².

The IllustrisTNG-project (or TNG in short) considers galaxy formation and evolution through large-scale cosmological hydrodynamical simulations (Springel et al. 2018; Marinacci et al. 2018; Nelson et al. 2018; Pillepich et al. 2018a; Naiman et al. 2018; Nelson et al. 2019a; Pillepich et al. 2019). Such simulations provide the tools to study parts of the Universe that are not easily accessible by observations. In particular of interest for this work, they simulate the high redshift enrichment of galaxies and the tail of low metallicity star formation at low redshift.

The models implemented in the publicly available 250 ²⁵¹ TNG simulations (Nelson et al. 2019b)³ have lead to 252 many successes. These models where calibrated at the resolution of the TNG100 simulation, hence TNG100 is ²⁵⁴ expected to provide the best overall agreement to global ₂₅₅ properties (like the star formation rate density). This why we adopt the TNG100 simulation as our fidu-257 cial simulation. For a more extended discussion focused on the processes that govern the creation, distribution 259 and mixing of metals in in the TNG simulations, we re-260 fer to Pakmor et al. (2022). In short, star formation in the TNG simulations is calibrated against the Kenni-262 cutt-Schmidt relation (Schmidt 1959; Kennicutt 1989), 263 using an effective equation of state (Springel & Hernquist 2003). The stellar metallicity yields are an updated version of the original Illustris simulations as de-266 scribed in Pillepich et al. (2018b). Star particles deposit 267 metals into the gas through type Ia and type II supernovae, as well as through asymptotic giant branch stars. The TNG simulations have been shown to match observational constraints on the mass-metallicity relation of galaxies up to z=2 (Torrey et al. 2019), as well as iron 272 abundances (Naiman et al. 2018), metallicity gradients 273 within galaxies at low redshift (Hemler et al. 2021), and 274 the reduction of star formation in the centers of starforming galaxies (Nelson et al. 2021). Several studies 276 have used the TNG simulations to make predictions for 277 astronomical transient sources (e.g. Briel et al. 2022a; 278 Bayera et al. 2022; van Son et al. 2022). Out of the four $\mathcal{S}(Z,z)$ variations explored, Briel et al. (2022a) find that 280 TNG provides one of the best agreements between ob²⁸¹ served and predicted cosmic rates for electromagnetic ²⁸² and gravitational-wave transients, when combined with ²⁸³ their fiducial binary population synthesis model.

On the other hand, large uncertainties and crude ap-285 proximations remain in all contemporary cosmological 286 simulations, thus also in the TNG simulations. Gen-287 erally, some of the chemical evolution of galaxies in 288 cosmological simulations is unresolved, and thus de-289 pends strongly on the implemented 'sub-grid physics'. 290 A known uncertainty is that dust is not included in the ²⁹¹ TNG simulations, which could mean that metallicity of 292 the star-forming gas is overestimated. Feedback from ac-293 tive galactic nuclei is not well understood theoretically ²⁹⁴ and is described in an approximate manner (Springel 295 et al. 2005; Weinberger et al. 2017). Furthermore, all 296 stellar winds mass loss from massive stars, binary inter-297 actions and their ionising effects are ignored (e.g. Dray 298 et al. 2003; Smith 2014; Götberg et al. 2020; Doughty & ²⁹⁹ Finlator 2021; Farmer et al. 2021; Goswami et al. 2022). 300 Moreover, the uniform ionising UV background is turned 301 on abruptly at z=6. This crucially impacts the amount 302 of low metallicity star formation at high redshift as it 303 allows small galaxies to produce more stars than what 304 would be expected for a gradually increasing UV back-305 ground that reaches full strength at z = 6. All these 306 uncertainties underline the need for a flexible approximation of the S(Z,z), that can be easily updated when 308 cosmological models and sub-grid physics are updated.

3.2. Choices and binning of the data

309

321

We fit equation 1 to the metallicity-dependent star formation rate of the star-forming gas in the TNG100 simulation. For this we use a binned version of the TNG data $S(Z,z)_{\rm sim}$. We consider metallicities between $\log_{10} Z = -5$ to $\log_{10} Z = 0$ in 30 bins, where we use $\log_{10} Z = 0$ in 30 bins, where we use $\log_{10} Z = 0$ in metallicities $\log_{10} Z \leq -5$ as this accounts for less than 1% of the total cosmic star formation rate in these simulations. We consider bins in redshifts between z = 0 and z = 10, with a step size of dz = 0.05, where z_j refers to the centres of the bins.

3.3. Optimisation function

To find a solution we use a method based on the sum of the quadratic differences between the simulations and our fit function. Using a vanilla χ -squared approach does not serve our purposes very well as it does a poor job in fitting regions where the star formation is very low. Using a χ -squared approach on the logarithm of the function instead places far too much weight on trying to fit the star formation rate in regions where the rate is very low or not even significant. After experimenting,

³ https://www.tng-project.org/

331 we find that the following approach gives us satisfactory
332 results.

We first consider a given redshift z_j . For this redshift we compute the sum of the squared residuals between the cosmological simulation and our fit. This is effectively the square of the l^2 -norm:

$$\chi^2(z_j) \equiv \sum_{Z_i} \left(\mathcal{S}(Z_i, z_j)_{\text{sim}} - \mathcal{S}(Z_i, z_j)_{\text{fit}} \right)^2. \tag{13}$$

Here, the variable Z_i runs over all metallicity bins. We are particularly interested in properly fitting the low metallicity star formation at high redshifts. At high redshifts, the overall star-formation rate density is generally lower. To ensure that our fitting procedure gives sufficient weight to the behaviour at all redshifts, we insufficient weight to the behaviour at all redshifts, we incontribution of redshifts where the peak of cosmic star formation occurs, while increasing the weight at redshifts where the overall star-formation rate density is lower. To achieve this we divide $\chi^2(z_j)$ by the star formation $\sum_{Z_i} \mathcal{S}(Z_i, z_j)$ per redshift bin before adding the contribution of all redshifts. Our final expression for the cost function reads

$$\chi = \sum_{z_j} \frac{\chi^2(z_j)}{\sum_{Z_i} \mathcal{S}(Z_i, z_j)}$$
 (14)

To minimize this cost funciton, we use scipy optimize.minimize from SciPy v1.6.3 which mplements the quasi-Newton method of Broyden, Fletcher, Goldfarb, and Shanno (BFGS, Nocedal & Wright 2006).

352

358

3.4. Resulting S(Z,z)

Our best fitting parameters are listed in Table 1. With these fit parameters, $\chi^2(z_j)$ is smaller than $2 \cdot 10^{-4}$ at any given redshift. To evaluate our fit, we show the residuals in Appendix A. We will refer to the $\mathcal{S}(Z,z)$ with the parameters listed in Table 1 as our fiducial model.

In Figure 1 we show our fiducial model at different red-366 shifts and metallicities. We also show the overall star-367 formation rate density SFRD(z) in Figure 2. In general, 368 our analytical model captures the metallicity-dependent 369 cosmic star formation history in the TNG100 simula-370 tions well (bottom panels of Figure 1). The skewed-371 log normal metallicity distribution is able to reproduce 372 the overall behaviour that is observed in TNG100 (bot-373 tom left panel, but cf. Pakmor et al. 2022, for an in-374 depth discussion of low metallicity star formation in the 375 TNG50 simulation). Only minor features like the addi- 376 tional bump just above $\log_{10}(Z)=-2$ at redshift 2 are 377 missed. However, for our purposes, it is more important 378 to prioritise fitting the large scale trends, while we are 379 not so interested in smaller scale fluctuations.

Adopting a skewed-lognormal metallicity distribution allows for a tail of low metallicity star formation out to low redshifts. To emphasise the difference between a skewed-lognormal and a symmetric lognormal distribution, we show the phenomenological model from Neijssel et al. (2019) in dotted grey. Their model falls within the family of functions that is encompassed by our model described in Section 2, but we note that their model is distinctly different.

Although our model preforms well at reproducing the 390 large scale trends seen in TNG, we acknowledge that 391 more complex features as suggested by some observa-392 tional studies could be missed. One example is that 393 the SFRD(z) shape we adopt from Madau & Dickinson 394 (2014) does not account for starburst galaxies (see dis-395 cussion in Chruślińska et al. 2021). Moreover, our model 396 cannot capture inflection points in the mean metallicity, ₃₉₇ because we assume both μ_0 and μ_z are constants with 398 redshift (equation 7). Contrarily, Chruślińska & Nelemans (2019) find an upturn in the amount of low metal-400 licity star formation above z = 4 if the power law of 401 the GSMF is allowed to evolve with redshift. Hence, 402 although our model is more broadly applicable than 403 previous models, in it's current form, it does not cap-404 ture the complete range of observationally-allowed varia-405 tions. Incorporating more complex functional forms for 406 our the mean metallicity could possibly capture such 407 behaviour, but this analysis is beyond the scope of this 408 paper.

409 4. APPLICATION: SYSTEMATIC VARIATIONS OF 410 $\mathcal{S}(Z,z)$ AND THE EFFECT ON THE MASS 411 DISTRIBUTION OF MERGING BBHS

We will now demonstrate the application of our analytical model by systematically varying the parameters in our fiducial S(Z,z) model, and investigate their effect on the local mass distribution of BBH mergers originating from isolated binaries.

We use the publicly available rapid binary population synthesis simulations presented in van Son (2022).⁵ These simulations were run using version v02.26.03

⁴ The phenomenological model from Neijssel et al. (2019) is recovered by adopting $\mu_0=0.035,~\mu_z=-0.23,~\omega_0=0.39,~\omega_z=0,~\alpha=0,~a=0.01,~b=2.77,~c=2.9$ and d=4.7.

 $^{^5}$ Available for download at https://sandbox.zenodo.org/record/ $1101303,\,{\rm see}$ also the Software and Data section in the acknowledgements

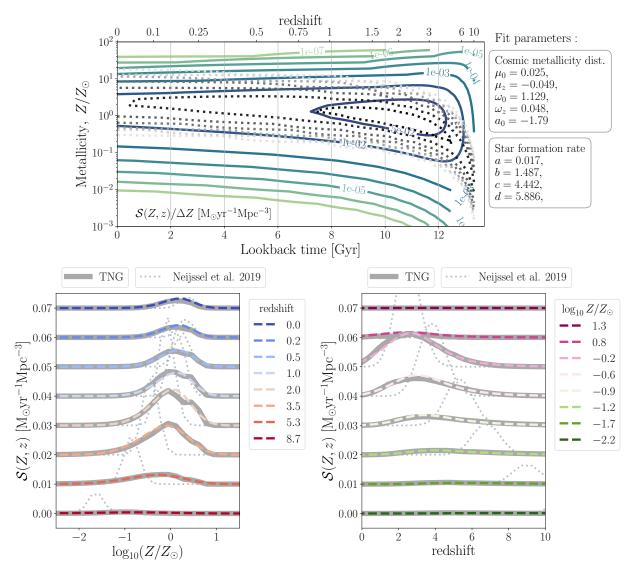

Figure 1. Our fiducial S(Z,z) model, adopting the best fitting parameters (listed on the top right) to fit the TNG100 simulations. The top panel shows the full two dimensional S(Z,z) linear in time. Contours range from $10^{-7}-10^{-2}\mathrm{M}_{\odot}\,\mathrm{yr}^{-1}\,\mathrm{Mpc}^{-3}$. The bottom left (right) panel shows slices of the distribution in redshift (metallicity). Each slice is displaced by $0.01\mathrm{M}_{\odot}\,\mathrm{yr}^{-1}\,\mathrm{Mpc}^{-3}$ (note the linear scale of S(Z,z) in the bottom panel). We show the TNG100 simulation data with thick gray lines. For comparison, we also show the phenomenological model from Neijssel et al. (2019) in all panels with grey dotted lines. The bottom panels show that our analytical model adequately captures the shape of the S(Z,z) from TNG100.

420 of the open source COMPAS suite (Riley et al. 2022)⁶.
421 COMPAS is based on algorithms that model the evolution
422 of massive binary stars following Hurley et al. (2000,
423 2002) using detailed evolutionary models by Pols et al.
424 (1998). In particular, we use the simulations be425 hind Figure 1 from van Son (2022), and we refer
426 the reader to their methods section for a detailed
427 description of the adopted physics parameters

⁴²⁸ and assumptions.⁷ Metallicities of each binary system ⁴²⁹ were sampled from a smooth probability distribution to ⁴³⁰ avoid artificial peaks in the BH mass distribution (e.g. ⁴³¹ Dominik et al. 2015; Kummer 2020). These simulations ⁴³² provide us with an estimate of the yield of BBH mergers ⁴³³ per unit of star-forming mass and metallicity.

 $^{^6}$ https://github.com/TeamCOMPAS/COMPAS

⁷ We note that the rate in van Son (2022) is slightly higher than the fiducial rate presented in Figure 3 in this work. This difference is caused by the use of rounded parameter values of S(Z, z) in van Son (2022).

dP/dZ	description	best fit	SFRD(z)	best fit
			$\mathrm{M}_{\odot}\mathrm{yr}^{-1}\mathrm{Mpc}^{-3}$	
μ_0	mean metallicity at $z = 0$	0.025 ± 0.036	a	0.02 ± 0.072
μ_z	z-dependence of the mean	-0.049 ± 0.006	b	1.48 ± 0.002
α	shape (skewness)	-1.778 ± 0.002	c	4.44 ± 0.001
ω_0	scale at $z = 0$	1.122 ± 0.001	d	5.90 ± 0.002
ω_z	z-dependence of the scale	0.049 ± 0.009		

Table 1. Best fitting parameters for our S(Z, z) fit to TNG100 data.

We combine the aforementioned yield with variations of the fiducial $\mathcal{S}(Z,z)$ model described in this work. By integrating over cosmic history, we obtain the local merger rates of BBH systems, which allow us to construct the distribution of source properties at every redshift. We use the cosmic integration scheme that is part the $\mathcal{S}(Z,z)$ model described in this work. The details of this framework are described in Neijssel et al. (2019), but also in van Son et al. (2022), where more similar settings to this work are used.

4.1. Determining reasonable variations of S(Z,z)

We consider variations in both the shape of the cosmic metallicity density distribution dP/dZ(Z,z), and the shape of the overall star-formation rate density, SFRD(z). To determine the range that is reasonably allowed by observations, we compare our variations to the observation-based S(Z,z) models described in Chruślińska et al. (2021). An overview of the explored variations is shown in Table 2. Below we explain how we arrive at these values.

For the cosmic metallicity density distribution, we vary every parameter that determines the shape of 457 dP/dZ(Z,z) independently (left two columns of Ta-458 ble 1), while keeping all other parameters fixed at 459 their fiducial value. For each variation, we inspect 460 the fraction of stellar mass that is formed at lowmetallicity ($Z < 0.1 Z_{\odot}$) versus the fraction of stel-462 lar mass that is formed at high-metallicity $(Z > Z_{\odot})$, 463 for all star formation that occurred below a certain 464 threshold redshift. We compare this to the models 465 from Chruślińska et al. (2021) in Figure 6 in Ap-466 pendix B. We have chosen our variations such that 467 they span a reasonable range of cosmic metallic-468 ity density distributions as allowed by observation-469 based and cosmological simulations-based models. We 470 use the models 214-f14SB-BiC_FMR270_F0H_z_dM.dat, 302-f14SB-Boco_FMR270_F0H_z_dM.dat from 471 and

Table 2. Variations on S(Z,z). For every variation, we either swap the value of an individual $\mathrm{dP}/\mathrm{dZ}(Z,z)$ parameter, or exchange the set of four $\mathrm{SFRD}(z)$ parameters, and replace them by the the min/max values listed here. All other parameters are kept fixed at their fiducial value.

	min	fiducial	max
dP/dZ(Z,z)			
μ_0	0.007	0.025	0.035
μ_z	0.0	-0.049	-0.5
α	-6.0	-1.778	0.0
ω_0	0.7	1.125	2.0
ω_z	0.0	0.048	0.1
SFRD(z)			
$(a,b \dots$	(0.01, 2.60)	(0.02, 1.48)	(0.03, 2.6)
c,d)	3.20, 6.20)	4.44, 5.90)	3.3, 5.9)

Chruślińska et al. $(2021)^8$ as a representation of a very low and high metallicity star formation realisation respectively. These models are the low and high metallicity extreme under their fiducial SFR—metallicity corresponding to them as chr21_lowZ and Chr21_highZ respectively from hereon. The difference between these models lies in the assumptions in the underlying empirical galaxy respectively from hereons. In general, low-mass galaxies contribute to low-metallicity star formation and shift the peak of S(Z,z) to lower metallicities. Chr21_lowZ is characterised by a star formation—galaxy mass relation that is flat at high galaxy masses (reducing the star formation rate for the highest-

⁸ These models including a detailed description of their contents are publicly available at https://ftp.science.ru.nl/astro/mchruslinska/Chruslinska_et_al_2021/

486 mass galaxies), a galaxy stellar mass function that evolves with redshift (predicting an in-488 creasing number density of low-mass galaxies), and a galaxy mass-metallicity relation following 490 Pettini & Pagel (2004). This model further ap-491 proximates the contribution of starburst galaxies 492 following Bisigello et al. (2018) and Caputi et al. (2017). Including starbursts shift the peak of 494 $\mathcal{S}(Z,z)$ to lower metallicities and broadens the 495 low metallicity part of the distribution. 496 the other hand, Chr21_highZ assumes the star 497 formation-galaxy mass relation does not flatten towards higher galaxy masses, a galaxy stellar 499 mass function that is constant over redshift, 500 and a galaxy mass-metallicity relation following 501 Kobulnicky & Kewley (2004). Lastly, this model 502 adopts the starburst prescription from Boco 503 et al. (2021), which produces results that are 504 similar to models without starburst galaxies.

For every variation of our model, we inspect both the full $\mathcal{S}(Z,z)$ and slices at redshifts z=0,0.5,3.0 and 6 by eye. At each slice we compare our model variation to Chr21_lowZ and Chr21_highZ, and ensure that none of our variations significantly exceeds these extremes in $\mathcal{S}(Z,z)$. This also serves as a sanity check for the overall star-formation rate density.

Lastly, we consider two variations of the overall star-512 formation rate density, SFRD(z), where we keep the metallicity distribution dP/dZ(Z,z) fixed, but vary all four SFRD(z) parameters at once (right two columns of Table 1). We use Figure 11 from Chruślińska et al. 517 (2021) to determine approximate upper and lower 518 bounds to the overall star-formation rate density. We 519 choose Madau & Fragos (2017) as an approximation of 520 the lower limit. For the upper limit, we use the upper 521 edge of models that adopt starbursts following $_{522}$ Bisigello et al. (2018) and Caputi et al. (2017) (SB: B18/C17), combined with a non-evolving low-₅₂₄ mass end of the galaxy stellar mass function (shown as 525 a thick brown line in Fig. 11 of Chruślińska et al. 2021, 526 and described in their table B1). To approximate these 527 models, we fit equation 12 by eye to the broken power 528 law description of this model as presented in appendix 529 B1 of Chruślińska et al. (2021). We show all SFRD(z)variations in Figure 2.

532 4.2. The effect of the $\mathcal{S}(Z,z)$ on the primary masses of merging BBH

To isolate the effect of the S(Z,z) from the effects of different formation channels, we split the data from van Son et al. (2022) between the stable mass trans-

fer channel (e.g., van den Heuvel et al. 2017; Inayoshi et al. 2017; Bavera et al. 2021; Marchant et al. 2021; Gallegos-Garcia et al. 2021; van Son et al. 2022), and the 'classical' common-envelope channel (or CE channel, e.g., Belczynski et al. 2007; Postnov & Yungelson 2014; Belczynski et al. 2016; Vigna-Gómez et al. 2018). These channels are distinguished based on whether the binary system has experienced a common envelope phase (CE channel) or only stable mass transfer (stable channel in short from now on).

547

In Figures 3 and 4, we show the resulting primary mass distribution of merging BBHs from the stable channel and CE channel respectively. The primary (section ondary) component refers to the more (less) massive component of merging BBHs. Each panel varies one aspect of the $\mathcal{S}(Z,z)$. In the first five panels of Figures 3 and 4, we vary one of the parameters that determine the shape of the probability density distribution of metallicities, while keeping all other values fixed at their fiducial values. In the last panel of Figures 3 and 4, we vary the shape of the overall star-formation rate densities, SFRD(z), to one of the variations shown in Figure 2, while keeping the probability density distribution of metallicities fixed.

The first thing we note is that the location of the 563 features in the primary mass distribution are robust against variations in S(Z,z). For the stable channel, 565 two features are visible in all variations: a peak at $_{566}~M_{\rm BH,1} \approx 9 {\rm M}_{\odot}$ and a bump at $M_{\rm BH,1} \approx 22 {\rm M}_{\odot}$. Two 567 more features are visible in at the high mass end for almost all S(Z,z); a knee at $M_{\rm BH,1} \approx 35 {\rm M}_{\odot}$ and another ₅₆₉ bump at $M_{\rm BH,1} \approx 45 {\rm M}_{\odot}$. Although the locations of 570 these features are constant, the features themselves can 571 disappear for variations that suppress the rate of high 572 mass BHs (e.g., dashed lines in the top panels of Fig. 573 3). Similarly, the CE channel displays a kink in the dis-574 tribution at about 9M_☉, and a peak at approximately $_{575}~M_{\rm BH,1} \approx 17 {
m M}_{\odot}$ for all variations. The latter peak is 576 the global peak of the mass distribution in almost all 577 variations.

The finding that the locations of features in the mass distribution do not change for different $\mathcal{S}(Z,z)$ is consistent with earlier work. Recent work by Chruślińska (2022) showed that, when comparing two very different models of $\mathcal{S}(Z,z)$ (their Figure 5), the location of the peaks remains the same, even though the normalisation between the two BBH merger rates is completely different. Furthermore, Broekgaarden et al. (2021) show the probability distribution of chirp masses for BBHs in their Fig. 4. Although features can disappear when the $\mathcal{S}(Z,z)$ prohibits the formation of certain (typically

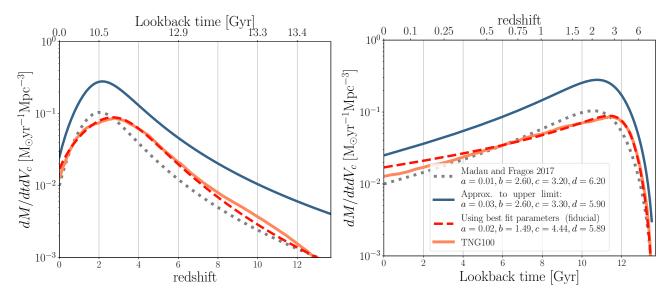

Figure 2. Comparison of several overall star-formation rate densities, SFRD(z), with redshift (left panel) and with lookback time (right panel). The solid orange and dashed red lines respectively show the star formation data from TNG100 and our corresponding fit adopting eq. 12 (fiducial model). The dotted gray and solid blue lines are variations of eq. 12 used to approximate the lower and upper edge of possible star-formation histories. The dotted gray line shows the model from Madau & Fragos (2017), while the solid blue line mimics the behaviour of the powerlaw-fit to the SB: B18/C17 variations with a non-evolving low-mass end of the galaxy stellar mass function from Chruślińska et al. (2021).

higher) mass BHs, the *location* of features remains the same. This implies that the locations of features in the mass distribution of BBHs are determined by the formation channel and its underlying stellar and binary physics. The locations of features could therefore serve as sign posts of the underlying physics.

Second, we see that the low mass end of the pri-596 597 mary mass distribution is relatively robust against vari-598 ations in S(Z,z). To quantify this, we annotate the ratio between the maximum and minimum rate at three $_{\rm 600}$ reference masses; $M_{\rm BH,1}=10,25,$ and $40{\rm M}_{\odot}.$ At $_{601}~M_{
m BH,1}=10{
m M}_{\odot},$ we find that the rate changes by at 602 most a factor of about 3.7 for the stable channel, and 603 at most about a factor of 3.8 for the CE channel. On the other hand, the change in rate at $M_{\rm BH,1}=40{\rm M}_{\odot}$ 605 can be as high as a factor of about 200 and 150 for the 606 stable and CE channels, respectively. The lowest mass 607 BHs are least affected by the S(Z,z) because they can be formed from all metallicities above $Z\gtrsim 10^{-3}$ (see 609 e.g., Figures 7 and 13 from van Son et al. 2022). The for rate of star formation at metallicities above $\gtrsim 10^{-3}$ is 611 observationally relatively well constrained for redshifts 612 below 0.5 (which comprises the past 5 Gyr of star for-613 mation). This is reflected in the top panel of Figure $_{614}$ 6: all models show that 10% or less of the stellar mass 615 was formed at a metallicity below $Z/10 \approx 0.0014$, or 616 in other words, about 90% or more of the stellar mass was formed at a metallicity above $\mathbb{Z}/10$. Hence the low618 est mass BHs derive from the least uncertain parts of 619 the S(Z,z). The low-mass end of the mass distribution 620 of merging double compact objects will also provide a 621 particularly powerful cosmological constraint in the era 622 of third generation gravitational wave telescopes (María 623 Ezquiaga & Holz 2022). Our finding that the low mass 624 end is more robust against variations in S(Z,z) supports 625 this claim.

Parameter variations that affect shape of S(Z,z) at 627 low redshift primarily change the normalisation of the 628 mass distribution. This is the case for variations of the 629 width of the cosmic metallicity density distribution at ₆₃₀ z=0 (ω_0), the mean metallicity of the cosmic metal-631 licity density distribution at z=0 (μ_0), and the skew-632 ness of the cosmic metallicity density distribution (α . 633 left columns of Figures 3 and 4). To emphasise this 634 point, we annotate the total BBH merger rate at redshift 635 0.2, $\mathcal{R}_{0.2}$, in the legends of Figures 3 and 4 (0.2 is the 636 redshift where the observations are best constrained Ab-637 bott et al. 2021b). Variations that increase the amount 638 of star formation at low metallicity (i.e. for a low mean 639 metallicity $\mu_0=0.007$ and a wide metallicity distribution $\omega_0 = 2.0$) increase the predicted BBH merger rate. 641 This is consistent with other work that finds merging 642 BBHs form more efficiently at low metallicities (e.g. Bel-643 czynski et al. 2010; Stevenson et al. 2017; Mapelli et al. 644 2017; Chruślińska et al. 2019; Broekgaarden et al. 2021). 645 A more skewed cosmic metallicity density distribution 646 pushes the peak of the distribution to higher metallici-

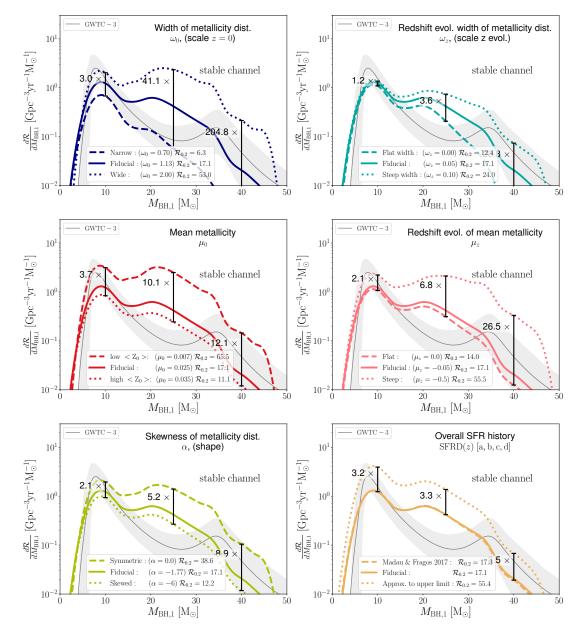

Figure 3. The primary mass distribution of merging BBH systems from the stable mass transfer channel for several variations in S(Z,z). The first five panels show variations of the cosmic metallicity density distribution dP/dZ(Z,z), eq. 11, (parameters listed in the first three columns of Table 1), where we vary one parameter at a time while keeping the rest fixed at their fiducial value. The bottom right panel shows variations in the magnitude of the star formation rate with redshift; i.e. SFRD(z). For the latter we vary the four fiducial parameters of SFRD(z) simultaneously (last two columns of Table 1). All panels are shown at a reference redshift of z=0.2, with the corresponding predicted BBH merger rate indicated in the legend. For reference, we show the power-law + peak model from Abbott et al. (2021b) in grey. We annotate the relative change in the rate at three reference masses: $10M_{\odot}$, $25M_{\odot}$ and $40M_{\odot}$.

ties and thus forms more stars at high metallicity when compared to a symmetric distribution. Hence, the local rate of BBH mergers is lower for the skewed distribution ($\alpha=-6$) with respect to the symmetric variation ($\alpha=0.0$).

Changing the overall star-formation rate density (SFRD(z), bottom right panels of Figures 3 and 4) also affects the normalisation of the mass distribution, but

has a smaller effect than the width and the mean of the cosmic metallicity density distribution at z=0 (ω_0 and This underlines the importance of the amount of low-metallicity star formation (e.g., Chruślińska 2022), and is furthermore in line with findings from Tang et al. Fragos (2020). As discussed in Section 4.1, we use Madau & Fragos (2017) and the solid blue line in Figure 2 as an approximate lower and upper bound to the SFRD(z)

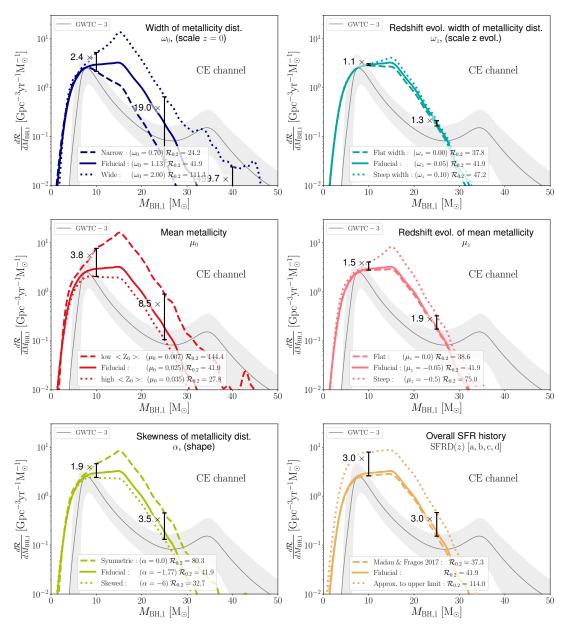

Figure 4. Same as Figure 3, but for the Common Envelope channel. These figures show that the low mass end of the primary mass distribution is least affected by the adopted S(Z, z). Moreover, the *location* of features in the mass distribution are robust against all explored variations.

⁶⁶³ respectively. The overall cosmic star formation rate density from Madau & Fragos (2017) is very similar to our fiducial model (Figure 2), and the differences between the resulting mass distributions are correspondingly small. Our approximation of the upper limit to the allowed SFRD(z) leads to an overall increase of the BBH merger rate by a factor of about 3.

Parameters that change the evolution of the metallicfri ity distribution dP/dZ(Z,z) with redshift, such as the redshift dependence of the with and mean; ω_z and μ_z fri (top right and centre right panels of Figures 3 and 4) primarily affect the high mass end of the stable channel. We understand this as an effect of the different delay time distributions for both formation channels. Since both, ω_z and μ_z influence the amount of low metallicity stellar mass formed at high redshifts they will mostly affect systems with longer delay times. The stable channel has been shown to produce more high mass BHs with longer delay times when compared to the CE channel (van Son et al. 2022; Briel et al. 2022b). Hence we find these variations affect the slope of the high mass end of the BBH mass distribution for the stable channel, while they have a relatively small impact on the CE channel.

5. DISCUSSION & SUMMARY

We present a flexible analytic expression for the metallicity-dependent cosmic star formation history, S(Z,z) (equations 1, 11 and 12). An analytical expression allows for controlled experiments of the effect of S(Z,z) on dependent values, such as the rate and mass distribution of merging BBHs. The model presented in this work adopts a skewed-lognormal for the distribution of metallicities at every redshift (dP/dZ(Z,z)).

The model can capture the general behaviour of cosmological simulations, such as TNG100—Our analytical expression for $\mathcal{S}(Z,z)$ is composed of a cosmic metallicity density 698 distribution that is determined by a mean, scale and 699 skewness and their redshift dependence, as well as pa-700 rameters governing the overall star-formation rate den-701 sity. We fit our analytical expression for $\mathcal{S}(Z,z)$ to the 702 star-forming gas in the TNG100 simulation, and provide 703 the best fit parameters in Table 1. We show that our 704 model captures the shape and general behaviour of the 705 cosmological simulations well (Figure 1). Although our 706 model is more broadly applicable than previous models, we acknowledge that it does not capture the complete 708 range of observationally-allowed variations in it's cur-709 rent form. Incorporating more complex functions for 710 the redshift evolution of the metallicity could solve this 711 issue, but this is left for future research.

The model allows for a controlled experiment on the effect of S(Z,z) on the local distribution of merging BBH—As an example, we use our model to calculate the local rate and mass distribution of the more massive components from merging BBHs $(M_{\rm BH,1})$ in Figures 3 and 4. We systematically vary all five parameters that shape the cosmic metallicity density distribution, and explore two additional variations of the overall star-formation rate density SFRD(z). Our main findings are as follows:

- The locations of features in the distribution of primary BH masses are robust against variations in S(Z, z). The location of features in the mass distribution of BHs could thus be used as sign posts of their formation channel.
- For all variations, the low mass end of the mass distribution is least influenced by changes in the S(Z,z). This is because the lowest mass BHs can be formed from all metallicities above $Z\gtrsim 10^{-3}$, for which the star formation rate is relatively well constrained in the recent Universe. This suggests that the lower end of the BH mass distribution (component masses of $\leq 15 \mathrm{M}_{\odot}$) is potentially very powerful for constraining the physics of the forma-

tion channels, irrespective of the cosmic star formation rate uncertainties.

- The metallicity distribution of star formation at low redshift primarily impacts the normalisation of the BBH merger rate. Changing the overall star-formation rate density, SFRD(z) also affects the rate, but to a lesser degree. This shows that low-metallicity star formation at low redshifts dominates the overall normalisation of the BBH merger rate.
- Parameters that influence the redshift evolution of the mean and the width of the metallicity distribution affect the slope of the high mass end of the primary BH mass distribution for the stable channel. This reflects the longer delay times of the stable channel with respect to the CE channel.

The flexibility of the model presented in this work can represented that remain in the shape and normalisation of the metallicity-dependent cosmic star formation history. Our hope is that this expression will provide a useful starting point for making predictions and comparisons with observations.

APPENDIX

A. EVALUATING OUR FIT; THE SQUARED RESIDUALS

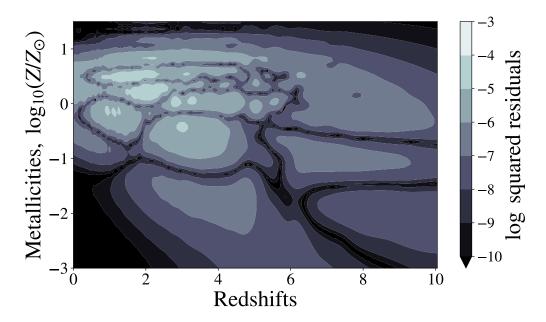

Figure 5. log of the squared residuals, which appear in equation 14 to optimise our fit.

In Figure 5 we show the log of the squared residuals. The residuals are the content of the sum regard in equation 13, which is used in the cost function, equation 14, to optimise our fit. We see that the maximum residuals appear just below the peak of star formation. We note that we chose to minimise the squared residuals (which is similar to minimising the mean squared error) in favour of e.g. minimising the relative error, to prevent overfitting regions of very low star-formation rate.

B. DETERMINING REASONABLE VARIATIONS OF THE S(Z, z)

To determine reasonable variations of our fiducial model for S(Z, z), we compute the fraction of low and high metallicity stellar mass formed for redshifts below z < 0.5, z < 3.0 and z < 10. We show the results in Figure 6, which is an adaptation of Fig. 2 in Pakmor et al. (2022), which in turn builds on Fig. 9 from Chruślińska & Nelemans (2019).

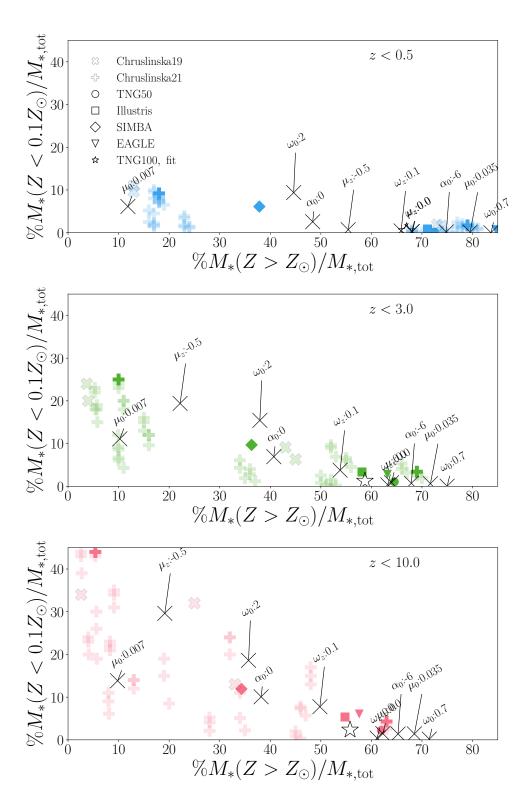

Figure 6. Percentage of stellar mass formed at low metallicity ($Z < 0.1Z_{\odot}$), versus high metallicity ($Z > Z_{\odot}$) for all star formation below a certain threshold redshift: z < 0.5 (top), z < 3.0 (middle) and z < 10 (bottom). Data from observation-based variations are shown with semi-transparent thick crosses, (Chruślińska & Nelemans 2019) and semi-transparent thick plus signs (Chruślińska et al. 2021), the low- and high-metallicity extremes are indicated with opaque symbols. For data from cosmological simulations, we follow Pakmor et al. (2022) and show Illustris (Vogelsberger et al. 2014, squares), Simba (Davé et al. 2019, diamonds), EAGLE (Schaye et al. 2015, triangles), TNG50 and TNG100 (Springel et al. 2018, filled and open circles respectively). Black thin crosses display variations of the cosmic metallicity density distribution that is part of our fiducial S(Z,z). The parameter that is varied with respect to the fiducial and its new value are annotated. This shows that our S(Z,z) variations span the range of reasonable cosmic metallicity density distributions as determined by observation-based and cosmological simulations-based models.
